ABSTRACT

We present a catalogue of 191 extragalactic sources detected by the Atacama Cosmology Telescope (ACT) at 148 and/or 218 GHz in the 2008 Southern survey. Flux densities span 14 – 1700 mJy, and we use source spectral indices derived using ACT-only data to divide our sources into two subpopulations: 167 radio galaxies powered by central active galactic nuclei (AGN) and 24 dusty star-forming galaxies (DSFGs). We cross-identify 97 per cent of our sources (166 of the AGN and 19 of the DSFGs) with those in currently available catalogues. When combined with flux densities from the Australia Telescope 20 GHz survey and follow-up observations with the Australia Telescope Compact Array, the synchrotron-dominated population is seen to exhibit a steepening of the slope of the spectral energy distribution from 20 to 148 GHz, with the trend continuing to 218 GHz. The ACT dust-dominated source population has a median spectral index, $\alpha_{148-218}$, of $3.7^{+0.62}_{-0.86}$, and includes both local galaxies and sources with redshift around 6. Dusty sources with no counterpart in existing catalogues likely belong to a recently discovered subpopulation of DSFGs lensed by foreground galaxies or galaxy groups.

Key words: methods: numerical – surveys – galaxies: active – galaxies: high-redshift.

1 INTRODUCTION

The technologies that enable observations of large numbers of millimetre and submillimetre sources were developed relatively recently. They open up for study a previously unexplored regime that has the power to reveal the evolution of underlying galaxy populations over cosmic time, and in particular over epochs of intense star formation. Instruments such as the Submillimeter Common-User Bolometer Array (SCUBA, SCUBA-2; Holland et al. 1999, 2013) operating at 850 μm , the Balloon-borne Large Aperture Submillimetre Telescope (BLAST; Pascale et al. 2008) operating at 250, 350 and 500 μm , the Large Apex Bolometer Camera (Siringo et al. 2009) operating at 870 μm and the AzTEC millimetre-wavelength camera (Wilson et al. 2008) operating at 1.1 and 2.1 mm have mapped up to 10 deg^2 of the sky, but greater coverage has been limited by the large amount of integration time required to conduct blind surveys to significant cosmological depth. Increased sky coverage and sensitivity motivated the construction of space-based observatories such as *Spitzer* (Werner et al. 2004) and *Herschel* (Pilbratt et al. 2010), operating in the wavelength regime 3–500 μm and covering up to tens of square degrees. At longer wavelengths, the *Wilkinson Microwave Anisotropy Probe* (WMAP; Wright et al. 2009) covered the whole sky at frequencies up to 94 GHz ($\lambda = 3.2$ mm), but observations of unresolved extragalactic sources were only complete above 2 Jy due to its large beam size (roughly 13 arcmin at 94 GHz). The *Planck* space telescope contains a high-frequency instrument observing at frequencies spanning 100–857 GHz (Lamarre et al. 2010). At 143 and 217 GHz (2.1 and 1.4 mm), the *Planck* beam sizes are approximately 7 and 5 arcmin, respectively, allowing for a source catalogue that is complete down to flux densities of about 1 Jy. Large-area ($>100 \text{ deg}^2$) ground-based radio surveys probe with higher resolution than WMAP or *Planck*, but only as high in frequency as 20 GHz (e.g. the Australia Telescope 20 GHz survey; Murphy et al. 2010). Thus, there is a niche for millimetre-wavelength large-scale mapping experiments with spatial resolution superior to that of the space-based observatories.

One such experiment is the Atacama Cosmology Telescope (ACT; Swetz et al. 2011). The ACT collaboration released cosmic microwave background (CMB) temperature anisotropy maps made with arcminute resolution from its 2008 observing season at 148 and 218 GHz (Dünner et al. 2013). These maps also contain galaxies that are luminous at millimetre wavelengths. Measurements of the millimetre fluxes of a large sample of sources have great potential to discriminate among source population models and reveal new source populations. For example, recent millimetre surveys (e.g. Vieira et al. 2010; Marriage et al. 2011; Planck Collaboration VII 2013) have yielded source counts that led to updated source models (Tucci et al. 2011) and the discovery of a new class of high-flux dusty galaxies (this paper; Negrello et al. 2010; Vieira et al. 2010).

ACT-detected sources at flux densities greater than 20 mJy are predominantly blazars that have synchrotron-dominated spectral energy distributions (SEDs). These galaxies are powered by active galactic nuclei (AGN), central black holes that accrete nearby matter in a process that produces time-variable jets out of the plane of the accretion disc; in the case of blazars, the jet direction lies close to our line of sight. Ejected ionized particles spiralling around magnetic field lines in the jets create the observed synchrotron emission. The study of blazar SEDs and source counts provides information about AGN physics (e.g. de Zotti et al. 2010; Planck Collaboration XV 2011; Tucci et al. 2011).

The second population identified at ACT wavelengths is comprised of infrared-luminous, dusty star-forming galaxies (DSFGs), which exhibit modified blackbody emission at submillimetre to millimetre wavelengths, diminishing towards longer wavelengths. The observed SED is dominated by thermal emission from dust grains that have been heated by the prodigious optical and ultraviolet flux produced by newly formed stars (e.g. Draine 2003, and references therein). A fraction of these galaxies may have a significant non-thermal contribution from AGN at their cores, in addition to the thermal dust emission.

Some of these DSFGs are local galaxies ($z \ll 1$), cross-identified with *Infrared Astronomical Satellite* (IRAS) sources (Devereux & Young 1990). The IRAS wavebands ($\lambda = 12\text{--}100 \mu\text{m}$) are relatively insensitive to dust with temperatures below 30 K, a significant and largely unexplored component of many nearby galaxies (Planck Collaboration XVI 2011). Recent results from *Herschel* (Amblard et al. 2010) and BLAST (Wiebe et al. 2009) have begun to extend our picture of the cold dust in galaxies, but millimetre-wavelength experiments can, through probing dust in nearby galaxies, contribute to establishing a well-calibrated dust SED for typical, low-redshift DSFGs. This in turn has cosmological ramifications, as current analyses of the first generations of stars and galaxies that fuel the cosmic infrared background (CIB) rely on understanding and extrapolating from dust SED templates.

High-redshift DSFGs were observed by SCUBA in the first systematic survey of these sources, which create a significant fraction of the CIB emission (Blain et al. 2002). Selected at 850 μm , these sources came to be known as submillimetre galaxies (SMGs). This new population of galaxies subsequently became a focus of observations (e.g. Viero et al. 2009; Weiß et al. 2009; Austermann et al. 2010) and stacking analyses that resolved more of the CIB into emission from discrete, DSFGs (e.g. Dole et al. 2006; Devlin et al. 2009). Though most SMGs will be undetectable by current millimetre survey instruments, a new population of sources that are significantly brighter and rarer than the submillimetre-selected SMGs and that similarly exhibit dust-dominated spectral indices has been identified at millimetre wavelengths (Vieira et al. 2010). They do not have counterparts in the IRAS catalogue, indicating that they are not members of the standard, local, ultraluminous infrared galaxy (ULIRG) population.

These sources have recently been shown to be a new, higher redshift ($z > 3$) subpopulation of the progenitor galaxy background, brought to the fore in millimetre-wavelength surveys because they are lensed by foreground galaxies or galaxy groups (Negrello et al. 2007, 2010; Lima et al. 2010; Hezaveh et al. 2013; Vieira et al. 2013). Such objects are extremely rare (at submillimetre wavelengths, for example, see Rex et al. 2010; Lupu et al. 2012), but wide-area surveys will find more. The South Pole Telescope (SPT; Carlstrom et al. 2011) has reported significant numbers of these sources. This population provides an avenue for follow-up research to study the details not only of lensed SMGs, but also of the lens systems (e.g. Ikarashi et al. 2011; Scott et al. 2011; Lupu et al. 2012; Weiß et al. 2013).

In this paper, we report for the first time the discovery of DSFGs in the ACT data. This is the first multifrequency analysis of the ACT sources and the second report on ACT extragalactic sources. Marriage et al. (2011, hereafter M11) presented a catalogue of sources at 148 GHz only from the 455 deg^2 of the 2008 ACT Southern survey with the best uniformity and coverage. Here we extend those results to include 218 GHz (and updated 148 GHz) flux densities for the same 2008 ACT Southern survey region from the new

(Dünner et al. 2013, hereafter D13) data release maps. Future work will present sources detected in the ACT *equatorial strip*. Mapmaking of the ACT 277 GHz data set is currently underway.

The layout of the paper is as follows. Section 2 describes the 2008 season ACT observations and the reduction of raw data into maps, as well as follow-up observations made with the Australia Telescope Compact Array (ATCA). Section 3 details our method of source extraction. The source catalogue, including its astrometric and flux density accuracy, and its estimated completeness and purity, is discussed in Section 4. Section 5 compares our catalogue with currently available data sets; Section 6 gives the source number counts. Trends observed in the spectral indices of our source populations are analysed in Section 7. We conclude in Section 8 with a summary of our results.

2 OBSERVATIONS AND DATA

2.1 ACT observations

The ACT experiment (Swetz et al. 2011) is situated on the slopes of Cerro Toco in the Atacama Desert of Chile¹ at an elevation of 5190 m. ACT’s latitude gives access to both the northern and southern celestial hemispheres. Observations occurred simultaneously in three frequency bands, at 148 GHz (2.0 mm), 218 GHz (1.4 mm) and 277 GHz (1.1 mm) with angular resolutions of roughly 1.4, 1.0 and 0.9 arcmin, respectively. Observations of Saturn were used to determine beam profiles and pointing (Hincks et al. 2010; Hasselfield et al. 2013). From 2007 to 2010, ACT targeted two survey regions: the *southern strip* centred around $\delta = -52.5^\circ$ and the *equatorial strip* centred around $\delta = 0^\circ$. Further information about the ACT observations can be found in D13.

2.2 ACT data

The reduction of raw ACT data into maps is detailed in D13; we will briefly review that process here. Each ACT detector array (one per frequency band) is composed of 1024 detectors, with each detector time stream first analysed and then kept or rejected based on multiple criteria, such as telescope operation, weather conditions, cosmic ray hits or other interference. Approximately 800 (700) h of data from the 2008 *southern strip* for 148 GHz (218 GHz) remain after these cuts.

Maximum likelihood maps of pixels 30 arcsec on a side are produced from the time stream data. From an initial estimate of the maps, source profiles are fitted for. We then subtract the time stream models for the point sources from the data and re-map. This prevents point source power from being aliased into the map, and improves the final flux density estimates for $S/N > 5$ sources (quantified below). Similarly, an estimate of the CMB signal is also removed. The mapping equation (Tegmark 1997) is then solved iteratively using the preconditioned conjugate gradient method. Finally, the signals that had been subtracted are added back to the map. We conducted simulations in which a signal corresponding to sources of known flux were injected into raw ACT detector time streams before mapping. The new mapping procedure with ‘source subtraction’ described briefly here and more thoroughly in D13 (Section 11.4) corrects a 3–5 per cent downward bias in the recovered flux densities.

The measured source flux densities have converged on a single value by the 25th iteration of the maps used in our study. For 148 GHz, the D13 release map is from iteration 1000 of the mapmaker, and we use this map both for convenience and in order that this study be exactly reproducible using public data. For our study of source flux densities at 218 GHz, we use iteration 200, which is more than adequate. Between the map iterations used in this study, the fluxes of the sources change less than 1 per cent. One may ask whether the value to which the measured source flux density has converged is accurate. Based on end-to-end simulations in which mock sources are injected into the ACT time streams, we estimate this accuracy at 3 per cent.

The 148 GHz map is calibrated in temperature through cross-comparison of spectra over the range $400 < \ell < 1000$ with *WMAP* as in Hajian et al. (2011) with an uncertainty of 2 per cent. This calibration is transferred to the 218 GHz map (2.4 per cent uncertainty) through cross-calibration with 148 GHz. Hasselfield et al. (2013, hereafter H13) used this calibration in measurements of the temperatures of Uranus and Saturn. The resulting planet temperature estimates were consistent with previous analyses (Griffin & Orton 1993; Goldin et al. 1997). To summarize the results of H13, both previous analyses adopted a flux standard based on a model of Mars (Wright 1976; Ulich 1981) with 5 per cent systematic errors. The H13 estimate for the temperature of Uranus and Saturn was 5 per cent below those of the previous analyses, a deficit which was also seen in the *WMAP* analysis of Weiland et al. (2011) at 94 GHz and is most likely due to systematic errors in the Mars standard. The agreement between the H13 analysis, calibrated on extended CMB emission, and the previous analyses, calibrated on Mars, lends confidence that the ACT *WMAP*-based calibration at large angular scales will also apply to the calibration of sources at small angular scales.

Photometry based on matched filtering (Section 3) relies on an accurate estimate of the instrument beam shape. The impact of beam error on photometry depends on the details of the filter (equation 1), which in turn depend on both the beam window function and the angular power spectrum of the background and noise. We have found that the error in the solid angle of the beam is a conservative proxy for the photometric error due to beam uncertainty, and we use this simpler quantity (solid angle uncertainty) in the beam-related photometry error estimates described here. Due to uncertainties in the beam measurements from Saturn, we assign 1 per cent photometric errors for both bands. The profiles of bright point sources in the survey maps suggest that the effective beam for the survey is slightly broader than that measured from Saturn. The survey maps consist of overlapping observations taken over the entire season, and the observed broadening may be attributed to a night-by-night jitter in the telescope pointing with an rms of 5 ± 1 arcsec (H13). The uncertainty in jitter correction corresponds to 1 per cent (148 GHz) and 2 per cent (218 GHz) photometric uncertainties, which are correlated between bands.

Finally, for our photometric uncertainty budget, we account for the fact that AGN have a lower effective frequency band centre (and thus slightly broader beam) than Saturn, and DSFGs have a higher effective frequency band centre (and thus narrower beam; Swetz et al. 2011, table 4). We choose effective 148 and 218 GHz frequency centres corresponding to half-way between a steep-spectrum AGN and a DSFG: 148.65 and 218.6 GHz. This choice introduces a photometric bias of less than 1.5 per cent at 148 GHz and 1.1 per cent at 218 GHz, which is positive for DSFGs and negative for steep-spectrum AGN. We add in quadrature this photometric bias from the source spectrum to uncertainties due to mapping (3 per cent), *WMAP*

¹ 22°586 south latitude, 67°7875 west longitude.

Figure 1. Sensitivity maps with source detections at 148 GHz (top) and 218 GHz (bottom), showing the most uniform 455 deg² patch of the *southern strip* with the greatest depth of coverage. It lies between right ascension 00^h 12^m and 07^h 07^m, and declination $-56^{\circ} 11'$ and $-49^{\circ} 00'$. The deepest data correspond to an exposure time of 23.5 min arcmin⁻² and a 1σ sensitivity of 2.34 mJy at 148 GHz and 3.66 mJy at 218 GHz. White circles or squares mark the locations of ACT sources with a size proportional to the log of the associated source flux density. Circles denote sources designated as AGN, and squares denote sources with spectra indicative of DSGFs. Towards the edges of the map, the variation in local noise properties due to uneven coverage is more apparent.

calibration (2 per cent, 2.4 per cent) and beam shape (1.4 per cent, 2.2 per cent) to obtain an overall flux density calibration uncertainty of 4.1 per cent at 148 GHz and 4.6 per cent at 218 GHz. As shown in Section 5, the ACT flux densities agree with independent measurements to within this margin of error.

For this study, we have used the most uniform 455 deg² of the 2008 ACT *southern strip* at 148 and 218 GHz. This region, shown in Fig. 1, spans declination $-56^{\circ} 2' < \delta < -49^{\circ} 0'$ and right ascension $00^{\text{h}} 12^{\text{m}} < \alpha < 07^{\text{h}} 07^{\text{m}}$. At 148 GHz, we use the data publicly released with D13.² Typical white noise levels in this region of the map are 30 $\mu\text{K arcmin}$ at 148 GHz and 50 $\mu\text{K arcmin}$ for 218 GHz. As described in Section 3, when matched-filtered with the ACT beam, this white noise level results in a 1σ point source flux density sensitivity in the best covered regions of $\sigma_0 = 2.34$ mJy at 148 GHz and 3.66 mJy at 218 GHz. The sensitivity levels in Fig. 1 are proportional to the square root of the number of observations at that map location, N_{obs} , with one observation per 0.005 s. Then the sensitivity level in a given portion of the map is $\sigma = \sigma_0 \sqrt{N_{\text{obs,max}}/N_{\text{obs}}}$.

2.3 ATCA observations

M11 found that the sample of ACT 148-GHz -detected sources cross-identified with the Australia Telescope 20 GHz (AT20G) survey (Murphy et al. 2010) is dominated by sources with peaked or falling SEDs using flux densities measured at 5, 20 and 148 GHz. The study also confirmed the findings of the AT20G study (Murphy et al. 2010; Massardi et al. 2011b), namely that this population of radio sources is characterized, on average, by spectral steepening between 20–30 GHz and 148 GHz. However, this sample from M11 was incomplete, biased in a way that favoured sources with negative spectral indices between 20 and 148 GHz due to the AT20G survey completeness level of 78 per cent above 50 mJy at 20 GHz. ACT-selected sources with 148 GHz flux densities less than 50 mJy and flat or rising spectra may not have been detected by AT20G. Therefore, in order to complete the M11 20–148 GHz spectral study, a targeted set of measurements of flux densities at 20 GHz was made

for the M11 sources that were not identified with any source in the AT20G catalogue within a 30 arcsec search radius.

Scheduling and weather constraints permitted us to observe 41 of these 48 sources with the 6 × 22 m antenna array of ATCA³ over 6.5 h at 20 GHz on 2010 November 10, when the array was in its east–west 750A configuration, with 15 baselines ranging from 77 to 3750 m. The primary beam of each array telescope at 20 GHz is 2.3 arcmin, with a resolution of 0.5 arcsec possible with the full array in this configuration. The synchrotron-dominated spectra of these sources, as revealed in M11, indicated that they were compact (AGN) and would be unresolved. For these observations, the two 2-GHz-wide frequency bands of the new ATCA Compact Array Broadband Backend (Wilson et al. 2011) digital array correlators were set to be adjacent by centring them at 19 and 21 GHz. The reduced average flux densities over the whole bandwidth of the correlator correspond to the ‘20 GHz’ flux density. Good weather conditions prevailed throughout the observations, from 07:35:24.9 UT through 14:11:54.9 UT. A few data blocks were flagged and removed in order to minimize noise and any spurious effects.

The primary flux calibrator used for these observations was PKS B1934–638, and the bandpass calibrator used was PKS B1921–293. The target sources were expected to have flux densities at or just below the AT20G survey limit of 40 mJy. Each target source was observed once for 1.5 min for an rms noise level of ≤ 0.15 mJy beam⁻¹. Target observations were interleaved with observations of four secondary calibrators for pointing and phase corrections, chosen to lie close to the targets.

2.4 ATCA data

The ATCA follow-up data were reduced using a fully automated, custom, shell script pipeline based on tasks from the MIRIAD aperture synthesis reduction package (Sault, Teuben & Wright 1995). An initial inspection of the data was performed to identify contamination or any problems in the data acquisition. Automatic procedures were used to identify and flag data for each frequency band affected by shadowing or known radio contamination, resulting in

² <http://lambda.gsfc.nasa.gov/product/act/>

³ <http://www.narrabri.atnf.csiro.au/>

less than 1 per cent of the band being flagged and cut. The pipeline then generated the calibration solutions for bandpass, flux density amplitude and phase based on the calibrators. After checking that results were consistent between the two frequency bands, we merged the calibrated target visibilities before extracting the flux densities to improve sensitivity.

Analyses of the AT20G survey (Murphy et al. 2010) and of other ATCA projects (Bonavera et al. 2011; Massardi et al. 2011a) have shown that the triple-correlation technique (Thompson, Moran & Swenson 1986) can be effectively used to determine source flux densities down to tenth of mJy scales for point-like sources unaffected by poor phase stability. This technique is effective for point sources even if they are not in the phase centre and in the case of low S/N.

We manually inspected the 20 GHz deconvolved images, and wherever a source was clearly identifiable we measured its flux density and flux density error at its peak in the image and the rms of the image pixels in a region unaffected by the source emission. For sources with high S/N, deconvolution techniques were able to reconstruct images, despite the poor uv-coverage of our observations. In the few cases where the source appeared extended with respect to the synthesized beam, we estimated the flux density by integrating over the source area. In some cases, the image showed a confused field with multiple peaks, primarily due to sidelobes; for these cases we extracted a flux density estimate using the triple-correlation technique. The flux density errors were obtained from the rms of the visibilities of the V Stokes parameter. This assumes that these objects have negligible circular polarization, which is an overestimate in the cases where the source is not in the phase centre. The same statistic (V Stokes rms) was used to indicate the noise level reached for fields where no source was identified at 20 GHz. Of the 41 ACT sources observed in the follow-up campaign described here, all had a measured flux density at 20 GHz. The final results of this study are included as part of Table 4 with asterisks indicating sources that were part of the follow-up ATCA sample.

3 ACT SOURCE EXTRACTION

We use the same matched filtering method as described in M11 to produce an estimate of the amplitude of a source at the location of the source centre. In this section, we summarize the method with an emphasis on aspects for which this analysis differs from M11.

Initially, the data are weighted by the square root of the number of observations per pixel. This method results in a map with an approximately constant white noise level and a natural apodization as the number of observations falls off towards the edge of the survey region. Using a new procedure, we filter the entire D13 148 GHz release map and corresponding 218 GHz map, both of which extend beyond the deep 455 deg² area of this study, in order to eliminate any potential edge effects. We then use only the 455 deg² region for source identification.

The following filter is applied to the Fourier transform of the map:

$$\Phi(\mathbf{k}) = \frac{F_{k_0, k_x}(\mathbf{k}) \tilde{B}^*(\mathbf{k}) |\tilde{T}_{\text{other}}(\mathbf{k})|^{-2}}{\int \tilde{B}^*(\mathbf{k}') F_{k_0, k_x}(\mathbf{k}') |\tilde{T}_{\text{other}}(\mathbf{k}')|^{-2} \tilde{B}(\mathbf{k}') d\mathbf{k}'}, \quad (1)$$

where $\mathbf{k} = (k_x, k_y)$ is the angular wavenumber, and x and y refer to the right ascension and declination directions. $B(\mathbf{k})$ is the Fourier transform of the ‘effective’ instrument beam. As described in Section 2, the ‘instantaneous’ beam is derived from planet observations (H13). The ‘effective beam’ in the 2008 survey map is broadened by imperfect telescope repointing with mean deviation

Figure 2. Matched filters (solid lines) are band pass filters that smooth the map on the scale of the beam (dashed lines) and remove large-scale structure associated with the CMB, other astrophysical signals (e.g. the Sunyaev–Zel’dovich effect) and residual contamination from atmospheric brightness fluctuations. The beam and filter functions are plotted with unit normalization at their peak ($\theta = 0$). The matched filters were binned in radius to better show the relevant angular scales. In the analysis, we use two-dimensional filters to capture the anisotropic character of the noise.

$\sigma_\theta = 5$ arcsec. This broadening is included in $B(\mathbf{k})$ by multiplying the instantaneous beam transform (released with D13 for 148 GHz) by $\exp(-\ell^2 \sigma_\theta^2 / 2)$. \tilde{T}_{other} is the Fourier transform of all components of the data besides point sources (i.e. atmospheric or detector noise, CMB, etc.). The function $F_{k_0, k_x}(\mathbf{k})$ is a high-pass filter that removes undersampled large-scale modes below $k_0 = 1000$ and modes with $|k_x| < 100$, which are contaminated in a fraction of ACT data by telescope scan-synchronous noise. While $B(\mathbf{k})$ is well approximated as azimuthally symmetric, we retain the full two-dimensional power spectrum $|\tilde{T}_{\text{other}}(\mathbf{k}')|^2$ to downweight anisotropic noise in the maps. The azimuthally binned 148 and 218 GHz real space filters and associated beam profiles are shown in Fig. 2.

The power spectrum $|\tilde{T}_{\text{other}}(\mathbf{k}')|^2$ used in this analysis was constructed in a different manner from M11: we used the power spectrum of the data itself instead of the average of difference (noise) maps and models for the CMB and other contaminating sky emission. This estimate is robust since the total power from the extragalactic source signal is low compared to the CMB, atmospheric noise and white noise. To avoid a noisy estimate of the power spectrum, we smooth the power spectrum $|\tilde{T}_{\text{other}}(\mathbf{k}')|^2$ with a Gaussian. The exact formulation of the smoothing does not significantly change the resulting filtered map.

Applying the matched filter can cause ringing in the maps around the very brightest sources, which impacts source extraction around other, low-S/N, sources. Therefore, we identify sources with $S/N > 50$ in an initial application of the filter, and mask them in the maps. Sources with $S/N < 50$ are then extracted by matched filtering these masked maps. Once filtered, groups of map pixels with $S/N > 4.8$ are identified as candidate sources, as illustrated in Fig. 3.

Finite map pixel size affects the measured flux densities, since it is rare that a source falls exactly in the centre of a pixel, leading to a systematic negative bias and increased scatter. We increase the map pixel resolution by a factor of 16 in a region 0:03 on a side around each source through Fourier space zero-padding (e.g. Press

Figure 3. Filtered 148 GHz (top) and 218 GHz (bottom) submaps. The data have been matched-filtered such that the grey-scale is in units of flux density (mJy) with white (black) corresponding to -10 mJy (30 mJy). Insets show the flux density distribution across the data as a grey histogram that has a standard deviation of 2.57 mJy (3.78 mJy) for 148 GHz (218 GHz). Several sources, both synchrotron and dust dominated, marked as circle and square outlines, respectively, are apparent as black beam-sized flux excesses. The white extended object in the 148 GHz map, marked by a diamond, shows the Sunyaev–Zel’dovich effect decrement from Abell 3128 NE (ACT-CL J0330–5228).

et al. 2007) to allow for a more precise determination of the source peak location, and therefore its flux density. Properly centring the detection has the effect of boosting the S/N of typical S/N = 4.8 sources to ≥ 5 . Lastly, to account for the convolution of sources with the map pixel, which acts as a low-pass filter (the square pixels become a sinc function in Fourier space), we deconvolve the map pixel window function in the higher resolution map. We find that this method reduces systematic errors associated with pixelization to below 1 per cent. Purity tests (Section 4.3) reveal a significant number of false detections below S/N of 5.0, due to local noise and striping artefacts. Therefore, we impose an S/N = 5.0 threshold on sources detected in each map assuming no prior knowledge of source location from the other frequency.

Once an S/N > 5.0 catalogue has been generated for each of the filtered 148 and 218 GHz maps, we look for sources that have been identified at one frequency but not the other. The flux density for the source at the second frequency is then measured from the filtered map for the second frequency. We use the same prescription as for the flux measurement method just described, using a submap at the second frequency centred on the location of the detection as determined from the map at the first frequency.

4 THE 148 AND 218 GHz CATALOGUE

The ACT-detected source catalogue is given in Table 4. We find 169 sources selected at 148 GHz with S/N > 5, spanning two decades in flux density, from 14 to 1700 mJy. The 218 GHz map independently yielded 133 sources with S/N > 5. The combination of these two independent source lists gives a total count of 191, with 110 galaxies detected with S/N > 5 at both frequencies.

The catalogue provides the IAU name, celestial coordinates (J2000), S/N and flux density estimation of each 148 and 218 GHz ACT-detected source. Raw flux densities are estimated directly from the map as described in Section 3. Deboosted flux densities as derived according to Section 4.2 are given with associated

68 percent confidence intervals. The raw and deboosted spectral indices, $\alpha_{148-218}$, between 148 and 218 GHz for each source, are provided. The classification of sources as dust or synchrotron dominated is based on the $\alpha_{148-218}$ spectral index criterion described in Section 4.2. If the source was cross-identified with an AT20G catalogue source (see Section 5), the AT20G source ID is given. If, instead, the 20 GHz source flux density was measured during the 2010 November follow-up campaign (Section 2.3), the 20 GHz ID name has an asterisk next to it. Sources not cross-identified with one of the catalogues listed in Section 5 are marked with a ‘d’ superscript.

Correlating 148 GHz flux densities between this catalogue and the catalogue given in M11, we find an average agreement at the 2 per cent level, with larger scatter for individual sources. This level of consistency is expected given changes in calibration, mapmaking, beam profile estimates and deboosting procedure made for this updated study.

The reported flux densities are the average over approximately two months of observation for each source, many of which are AGN-driven radio galaxies and thus likely to have varied in that time. For example, of the three bright sources cross-identified with *Planck*, in the year between ACT and *Planck* observations one source varied by 20 per cent in flux density whereas one did not vary at all within errors. However, our simultaneous multifrequency observations allow for a consistent internal spectral characterization between ACT bands. In a future study, multiple years of data will be used to quantify the effects of variability on individual source spectra.

The following sections provide details and context for the catalogue values.

4.1 Astrometric accuracy

Radio interferometers can achieve very precise positional accuracy for sources, so ACT-selected sources cross-identified with a robust radio catalogue give a good measure of the positional accuracy of the ACT source detections. The AT20G catalogue covers the southern sky, and through pointing checks against very long baseline interferometer measurements of International Celestial Reference Frame calibrators, the positional accuracy of AT20G is shown to be accurate to better than 1 arcsec (Murphy et al. 2010). We exclude nearby extended/resolved sources from this analysis, determined from cross-identification of our sources with currently available catalogues, as distant point-like sources will present a clearer picture of the overall accuracy of our pointing.

We compared the positions of the 34 ACT sources with S/N₁₄₈ > 16 to positions of associated sources in the AT20G catalogue using a search radius of half the ACT 148 GHz beam (0.7 arcmin). Fig. 4 shows the offsets in location between the AT20G right ascension (RA) and declination (Dec.) and the ACT-derived positions for the sources as they were detected in the 148 GHz (black points) and 218 GHz (blue points) maps. The results are also summarized in Table 1. The large overlaid error bars are centred on the mean offsets, and extend as far as the rms of the offsets. For sources with lower S/N, the ACT location rms with respect to the AT20G position becomes inflated by the effect of noise in the maps. Therefore, the catalogue uses coordinates derived from the 148 GHz map since there is a higher level of noise present in the 218 GHz map.

4.2 Flux density accuracy

Flux densities derived from the ACT maps have systematic uncertainties arising from five effects: the overall calibration uncertainty,

Figure 4. Astrometric accuracy of the ACT source detections. The 34 filled black circles denote the positional offsets of ACT sources with $S/N_{148} > 16$ from counterparts in the AT20G catalogue as calculated from the 148 GHz map. The turquoise triangles are for the same sources, but using positions derived from the 218 GHz map, which has more noise. The large error bars are centred on the mean offsets, and extend as far as the rms of the offsets. See Table 1.

Table 1. Astrometric pointing accuracy.

	148 GHz	218 GHz
Mean RA offset (arcsec)	0.6 ± 0.4	0.5 ± 0.6
Mean Dec. offset (arcsec)	-0.4 ± 0.3	0.0 ± 0.6
RMS in RA offset (arcsec)	2.1	3.5
RMS in Dec. offset (arcsec)	1.8	3.4

the mapmaker, errors in the assumed source profile, error in the assumed source spectrum and flux boosting of lower significance candidates. The first four potential sources of flux density error were discussed in Section 2. Here we will discuss the last source of flux density error.

The differential counts of the sources selected in our sample fall steeply with increasing flux (Table 2, Fig. 6). With no prior information about the source flux, the most likely scenario is that the measured flux is the sum of a dimmer intrinsic flux and a positive

noise fluctuation. We use the two-band Bayesian method developed in Crawford et al. (2010), and report the 16, 50 and 84 percentiles (68 per cent enclosed, equivalent to 1σ) of the posterior flux and spectral index distributions. For the source count priors in this calculation, we use the sum of the models of de Zotti et al. (2010) for radio sources (using the Tucci et al. 2011 model results in flux differences of $<0.03\sigma$) and Béthermin et al. (2011) for dust-dominated sources. Following Vieira et al. (2010), we take a flat prior on the spectral index between -3 and 5 , consistent with the expected range for our populations. The two-band likelihood includes negligible correlation between bands and is consistent with background astrophysical emission rather than correlated atmospheric emission.

The source populations in 148 and 218 GHz naturally split into sources having their emission dominated by synchrotron (centred on $\alpha = -0.6$) or thermal dust (centred on $\alpha = 3.7$; see Fig. 7, bottom panel). We use the threshold spectral index $\alpha = 1.66$ (Vieira et al. 2010) to divide these populations in terms of their posterior spectral index populations, with $P(\alpha > 1.66) > 0.5$ classified as dusty and $P(\alpha > 1.66) < 0.5$ as synchrotron dominated. The classification is robust within $\alpha \pm 0.5$ of this threshold. While calibration uncertainty is included in all quoted fluxes, we conservatively ignore inter-band correlation of calibration errors when flux deboosting to avoid making assumptions about the correlation of the pointing jitter, chromatic effects and mapping/flux recovery errors (Section 2.2). This moderately boosts the error on the spectral index towards high S/N, but does not impact our source identifications.

In addition to the bias from the steepness of the population, we also treat the fact that the source finder locates the maximum flux along RA and Dec., which provides an extra two degrees of freedom. This can be corrected by finding the flux after two degrees of freedom are subtracted from the detection significance, following Vanderlinde et al. (2010). Note that this departs from the treatment in Crawford et al. (2010) and Vieira et al. (2010). Specifically, all sources are corrected by a factor $(S/N)/\sqrt{S/N^2 - 2}$. For sources in the range 20–25 mJy, this is a correction of 0.5 per cent at 148 GHz and 1.5 per cent at 218 GHz. We have confirmed through simulations with synthetic sources implanted in the ACT data that this positional deboosting results in unbiased flux densities. Furthermore, we have compared raw flux densities from the matched filter to flux densities from the ACT data at the positions of ATCA counterparts, when available. The latter should not be boosted due to maximizing the flux over position in RA and Dec. As expected, we find that positional deboosting accounts for the ratio between

Table 2. Number counts, purity and completeness^a.

^aThe number of sources at each frequency with $S/N = 5$ over 455 deg². Errors on number count are simply Poisson. See Fig. 6 for a graph of purity/completeness-corrected differential source counts.

^bCounts of synchrotron-dominated sources are taken relative to the 148 GHz flux density.

^cCounts of dust-dominated sources are binned according to their 218 GHz flux density.

the raw flux densities and the flux densities derived using ATCA counterpart locations.

As a final consistency check, we note that for the sources observed by both ACT and *Planck*, flux densities are consistent at the ≈ 1 –2 per cent level, suggesting that the errors assumed here are very conservative and free from any systematic bias (Section 5.3).

4.3 Purity and completeness

The number of false detections at each frequency was estimated by running the detection algorithm on an inverted (negative temperature) map in which we masked the sources and, in the case of the 148 GHz map (for which the Sunyaev–Zel’dovich effect was non-zero), all ACT-detected and optically confirmed clusters of galaxies. With this approach, no spurious detections are found in the 148 GHz data down to an S/N of 5. In the 218 GHz data, four spurious detections at $S/N \leq 6$ were observed with raw flux densities in the 25–31 mJy range (Table 2).

The purity simulations appear to be consistent with our findings from source cross-identification (Section 5). At 148 GHz, only one 5σ source, ACT-S J023600–530237, is not cross-identified with other catalogues. At 218 GHz, five 5σ sources, ACT-S J024430–541605, ACT-S J035034–524801, ACT-S J062747–512614, ACT-S J063715–500414 and ACT-S J065207–551605, are not cross-identified with other catalogues, although we expect some of these to be real DSFGs, a hypothesis which will be tested through future follow-up observations.

In order to estimate completeness of the catalogue for each band, we added 100 synthetic sources of a single flux density to the 455 deg² region of the ACT maps used in this study. The map filtering and source detection algorithm (Section 3) were run, and the resulting catalogue checked for inclusion of the input sources. This procedure was repeated in each band in intervals of 10 mJy in synthetic source flux density in the range 10–100 mJy. The completeness at each flux density was interpolated to estimate the completeness in flux density bins given in Table 2.

5 COMPARISON TO OTHER CATALOGUES

To further characterize ACT sources, we consider cross-identifications with other catalogues. Given the number of ACT-detected sources and the ACT beam size, around 1 out of 10 000 sources randomly placed in the 455 deg² area considered here would coincide with an ACT source. Fig. 5 shows the ACT sources located in flux density space and cross-identifications from some overlapping catalogues with extragalactic source detections in the Southern hemisphere discussed in this section. The synchrotron-dominated sources occupy points near the power law $S_\nu \propto \nu^\alpha$ with spectral index $\alpha = -0.6$. Dust-dominated sources will follow a line closer to $\alpha = 3.7$, and are generally associated with sources detected with $S/N > 5$ at 218 GHz only.

As our cross-identifications come from radio catalogues at low frequencies, and dust-dominated sources lack strong synchrotron radiation, we expect fewer of the dust-dominated sources to be co-identified with a previously known radio source. Overlapping large-area, sensitive far-IR (FIR) catalogues would be the equivalent for our dust-dominated sources, but these do not exist. Even if they did, they would be too confused for positive cross-identification in this manner. At present, these unidentified sources are the subject of individual follow-up studies (e.g. Ikarashi et al. 2011; Scott et al. 2011; Lupu et al. 2012; Weiß et al. 2013).

Figure 5. The ACT sources cross-identified in flux density space. Sources have been selected with $S/N > 5.0$ in at least one frequency band (dotted lines). See the text for a more thorough description of cross-identification statistics with other catalogues. The diagonal lines follow the power law $S_\nu \propto \nu^\alpha$ with $\alpha = 1.66$ for the dashed line, distinguishing the $\alpha = -0.6$ (dash-dotted) synchrotron-dominated source population from the $\alpha = 3.7$ (dash-dot-dot) dust-dominated source population.

5.1 General statistics of identifications

Of our 191 sources, many have cross-identifications with several catalogues. 174 are identified with sources in the 0.84 GHz Sydney University Molonglo Sky Survey (SUMSS; Mauch et al. 2003), and 122 of those cross-identified sources also belong to the 4.85 GHz Parkes-MIT-NRAO survey radio catalogue (Wright et al. 1994). 14 sources were cross-identified with the *IRAS* (Helou et al. 1988) at 12–100 μ m. Sources were also identified with one or both of the AT20G survey (Murphy et al. 2010) and the 1.4/2.0 mm SPT (Vieira et al. 2010) catalogues. Two of the remaining eight unmatched sources were observed during the 2010 November ATCA follow-up campaign (Section 2.3). This leaves six sources (ACT-S J023600–530237, ACT-S J024430–541605, ACT-S J035034–524801, ACT-S J062747–512614, ACT-S J063715–500414 and ACT-S J065207–551605) with no identification in any of the available catalogues, all but one of which have dust-dominated spectra. The single unidentified source with a synchrotron spectrum, ACT-S J023600–530237, falls near our $S/N = 5$ threshold at 148 GHz and could be a false detection.

A NASA/IPAC Extragalactic Database (NED) search using a radius of 2 arcmin cross-identified three sources from the ACT catalogue with galaxy clusters: Abell S0250, Abell 3391 and S rsic 037/01. Increasing the search radius to 3 arcmin adds Abell 3128 and Abell 3395 to this list. Simulations of the microwave sky suggest that only ≈ 3 per cent of galaxy clusters have their 148 GHz signal contaminated at 20 per cent or more (Sehgal et al. 2010).

5.2 Matches to AT20G

The AT20G survey, carried out from 2004 to 2008 at 20 GHz with a follow-up at 5 and 8 GHz, covered 6.1 sr of the southern sky to a flux density limit of 40 mJy at 20 GHz (Murphy et al. 2010). Of our sources, 115 match sources in the AT20G catalogue, listed in

Table 4, all of which we classify as synchrotron dominated. Given the AT20G completeness limit and the predominance of flat spectra for our 148-GHz-selected sources (Section 7), faint ACT sources may not have matches in AT20G. We received time on the ATCA to measure flux densities for sources in the earlier M11 catalogue that did not appear in AT20G, the results of which are described in Sections 2.3 and 7.

5.3 Matches to the *Planck* compact source catalogues

The *Planck* satellite team has released two sets of all-sky catalogues in nine frequency channels, including two very close to those used by ACT. The first set of catalogues made up the Early Release Compact Source Catalog (Planck Collaboration XIII 2011). Very recently, a deeper catalogue based on 1.6 complete *Planck* surveys has been released, the Planck Catalog of Compact Sources (PCCS; Planck Collaboration XXVIII 2013). At 143 and 217 GHz, the *Planck* beam sizes are approximately 7 and 5, respectively. Like *WMAP*, *Planck* makes great gains by observing the entire sky simultaneously at several frequencies, thus capturing all bright sources. On the other hand, due to their large beam sizes, these experiments detect *only* the brightest sources. In the case of the PCCS, the detection threshold at 143 and 217 GHz is ≈ 400 mJy; at lower flux densities the catalogue completeness drops well below 80 per cent. In the area treated in this study, *Planck* detects three of the brightest ACT sources.

For a more complete comparison with the PCCS, we examined all bright ACT sources, combining the equatorial and southern regions mapped by ACT. Almost 50 matches were found in this wider comparison. At 148 GHz, the agreement between ACT flux densities and the PCCS flux densities, properly colour corrected and (slightly) extrapolated to match ACT's central frequency, is excellent, at the 1–2 per cent level, despite scatter introduced by source variability. At 218 GHz, source variability plays at least as large a role, and PCCS flux densities are ≈ 5 per cent higher than ACT's. If we remove a couple of the most variable sources, however, the agreement of the 218 GHz flux density scales improves to ≈ 1 per cent. At both frequencies, *Planck* fluxes are on average slightly higher. Agreement at the ≈ 1 –2 per cent level, however, is well within the expected uncertainty in the ACT flux densities (Section 2). This agreement suggests that our flux density values are free of systematic error.

5.4 Matches to the SPT catalogue

The SPT study of compact sources (Vieira et al. 2010) was based on observations of a square patch of sky of 87 deg^2 centred at 05^{h} right ascension, having only fractional ACT overlap. Nevertheless, 2304 of the 3496 SPT candidate sources (those with $S/N > 3$ and flux densities > 4.4 mJy) fall within the ACT survey region. We find 32 cross-identifications with ACT sources when we search the SPT 1.4 mm (220 GHz) and 2.0 mm (145 GHz) catalogues. 25 of these were 148 GHz selected and categorized in Vieira et al. (2010) as synchrotron dominated. The remaining seven were detected by ACT with $S/N > 5$ only at 218 GHz; three of the seven also have SUMSS or *IRAS* cross-identifications. To make a direct comparison of the flux densities of ACT-SPT cross-identified sources, we used our derived flux densities, but without introducing two angular degrees of freedom in the deboosting (as in Vanderlinde et al. 2010), as these were not incorporated by the SPT analysis (Crawford et al. 2010). We find an overall offset at the 7 ± 5 per cent level at 148 GHz and 3 ± 7 per cent at 218 GHz, with ACT flux densities typically higher

than those of SPT. At low flux, the ACT and SPT measurements of individual sources agree within their errors. However, at fluxes above 30 mJy, individual sources may disagree at several sigma. We understand the discrepancy to be due to variability in radio sources, which is deferred to a future publication.

Recently, using spectroscopic follow-up observations with the Atacama Large Millimeter/submillimeter Array (ALMA), Vieira et al. (2013) and Weiß et al. (2013) derived robust redshifts for about 18 of the SPT-detected dust-dominated sources from a larger sky area than in Vieira et al. (2010). One of these sources, found to be at redshift 5.66, matches ACT-S J034640–520505 which otherwise had no cross-identification. A second previously unmatched source, ACT-S J002707–500713, imaged with ALMA at $870 \mu\text{m}$, is resolved at the 0.5 arcsec scale, likely due to gravitational lensing, but awaits a spectroscopic follow-up. Four other ACT dust-dominated sources that were cross-identified with the Vieira et al. (2010) catalogue now also have robust redshifts. ACT-S J055139–505800 is at redshift 2.123, ACT-S J053250–504709 is at redshift 3.399, ACT-S J052903–543650 is a source at redshift 3.369, with a lens at redshift 0.140, and ACT-S J053817–503058 has a redshift of 2.782, with a lens at a redshift of 0.404. It is likely that the few ACT dust-dominated sources which lie outside the SPT footprint are also lensed DSFGs.

5.5 Matches to the *IRAS* catalogue

Given the ACT beam size, a normal galaxy will be unresolved at redshifts $z \geq 0.05$ or distances greater than 200 Mpc. Consequently, only very nearby objects appear extended in our maps. The *IRAS* source population consists primarily of local ($z \ll 1$) dust-dominated ULIRGs; we thus expect our resolved sources to coincide with *IRAS* sources. We find 14 sources cross-identified with *IRAS* sources, out of a possible 829 *IRAS* sources that lie within the ACT survey area treated here. Two of these have synchrotron-dominated spectra, both of which are nearby galaxies. The 12 that show spectra dominated by dust re-emission are Galactic sources, in the Magellanic Clouds, or are known nearby star-forming galaxies. For example, for two local resolved galaxies particularly bright at ACT frequencies, NGC 1566 (ACT-S J041959–545622), a Seyfert two-arm spiral, and IC 1954 (ACT-S J033133–515352), a late-type spiral with a short central bar, ACT observes a higher 218 GHz flux density than at 148 or 20 GHz, confirming the dust-dominated nature of their spectra.

5.6 Dust-dominated ACT sources

Of the 24 ACT dust-dominated sources in the catalogue presented here, 18 of these are cross-identified with either *IRAS* (12 sources) and/or SPT (9 sources, including the recent ALMA observations). ACT-S J051506–534420, ACT-S J053311–523827 and ACT-S J055115–533435 were cross-identified with both catalogues. 10 of the dust-dominated sources are cross-identified with sources in the SUMSS catalogue, bringing the total for cross-identified sources to 19. The remaining five sources, ACT-S J024430–541605, ACT-S J035034–524801, ACT-S J062747–512614, ACT-S J063715–500414 and ACT-S J065207–551605, have no matching counterpart, and signal-to-noise at 218 GHz in the range $5.27 < S/N < 6.35$. Purity tests suggest that a couple of these could be spurious. However, given that three $S/N \approx 6$ sources are cross-identified with SPT, some of these sources are likely real detections, high-redshift galaxies lensed

Figure 6. Differential number counts of ACT-selected sources. Derived from Table 2 and corrected for completeness, the ACT differential source counts are plotted together with models of radio and infrared source populations. The Planck Collaboration VII (2013) data points and the SPT data points of Vieira et al. (2010) are also plotted, both of which are consistent with ACT counts. The ACT and *Planck* points have Poissonian errors (1σ), whereas the SPT points include measurement and independent calibration errors. The FIR models on this scale predict number counts too low to be seen at 148 GHz. The ACT data are consistent with being dominated by radio sources at both frequencies.

by intervening structure. Future follow-up observations are planned to clarify the nature of these detections.

The main and supplementary 500 μm samples from the *Herschel* Multi-tiered Extragalactic Survey have lensing candidate densities of 0.14 ± 0.04 and $0.31 \pm 0.06 \text{ deg}^{-2}$, respectively (Wardlow et al. 2013). An analogous sample from *Herschel*'s H-ATLAS survey is $0.35 \pm 0.16 \text{ deg}^{-2}$ (Negrello et al. 2010). In the same bands as presented here, SPT finds $0.25 \pm 0.02 \text{ deg}^{-2}$ lensing candidates (Mocanu et al. 2013). This suggests that ≈ 100 such sources exist in the field here, of which we see the high-flux tail.

6 SOURCE COUNTS

The completeness-corrected differential number counts for ACT sources based on the data in Table 2 are plotted in Fig. 6. For comparison, completeness-corrected number counts from Vieira et al. (2010) and Planck Collaboration XIII (2011) are plotted as well. The ACT data fill in the flux density gap between the SPT and *Planck* catalogues at these frequencies, caused by the differences between experiments in sky coverage and sensitivity to point sources. The effect of calibration error is to shift the flux bins by ± 2 per cent (± 2.4 per cent) at 148 GHz (218 GHz; Section 2).

The combined ACT, SPT and *Planck* total counts at 148 GHz and synchrotron-dominated source counts at 218 GHz are best fitted by the recently developed Tucci et al. (2011) C2Ex radio source model. This model divides the \sim flat- or steep-spectrum blazar population into BL Lac objects, with a region close to the AGN core dominating the observed emission ($\leq 0.3 \text{ pc}$), and flat-spectrum radio quasars (FSRQs) with a break frequency indicating that the source of emission arises from an emitting region further from the AGN core (0.3–10 pc). The de Zotti et al. (2005) model for radio source counts, while consistent with the counts below 0.1 Jy,

overpredicts the counts at higher flux densities. *Planck* analysis finds that the de Zotti et al. (2005) model is consistent with their counts at frequencies up to 100 GHz, but overpredicts the counts at higher frequencies in the flux density region of $\approx 1 \text{ Jy}$, though they begin to suffer from incompleteness below $\approx 1 \text{ Jy}$. Our few $\approx 1 \text{ Jy}$ brightest sources appear to be consistent with this finding, but lend little statistical significance.

As well as the models for counts of radio sources, the source counts predicted for dusty starburst galaxies from Toffolatti et al. (1998), Lima et al. (2010), Béthermin et al. (2011) and Cai et al. (2013) are shown in Fig. 6. The brightest infrared sources in the Toffolatti et al. (1998) model are 10 mJy. Given that all sources in the ACT catalogue have flux densities greater than 10 mJy, these models predict that the 148- and 218-GHz-selected ACT catalogues should have few or no detected infrared sources. However, we find 24 sources that have dust-dominated spectra with flux densities above 20 mJy, and Vieira et al. (2010) find 36 dust-dominated sources with flux densities above 15 mJy. While Toffolatti et al. (1998) do not incorporate the effects of lensing on observed number counts, the models of Lima et al. (2010), Béthermin et al. (2011) and Cai et al. (2013) modelled dust-dominated galaxies together with lensed high-redshift dust-dominated galaxies. However, the small number of dust-dominated sources present in Fig. 6 lends little constraining power, and we leave it to future larger area ACT studies to analyse the robustness of these models. The Béthermin et al. (2011) model, falling roughly in the middle of this group of models, was used for our flux deboosting.

7 SOURCE SPECTRA

Source SEDs can be used to differentiate source types by their dominant emission mechanisms. Assuming the commonly used simple

Table 3. Median spectral indices.

Spectral index	Synchrotron (all) ^a	Synchrotron ($S_{148} > 50$ mJy)	Synchrotron ($S_{148} < 50$ mJy)	Dust-dominated
α_{5-20}	$-0.15^{+0.37}_{-0.36}$	$-0.07^{+0.36}_{-0.25}$	$-0.21^{+0.33}_{-0.41}$	–
α_{20-148}	$-0.42^{+0.32}_{-0.26}$	$-0.36^{+0.24}_{-0.29}$	$-0.43^{+0.34}_{-0.33}$	–
$\alpha_{148-218}$	$-0.55^{+0.60}_{-0.60}$	$-0.60^{+0.20}_{-0.20}$	$-0.51^{+0.38}_{-0.71}$	$3.7^{+0.62}_{-0.86}$

^aQuoted errors are the 68 per cent confidence levels of the distribution.

power-law model $S(\nu) \propto \nu^\alpha$, a negative α is indicative of sources dominated by synchrotron emission, such as radio galaxies. Sources with free-free emission dominating will have an index close to 0. The high-redshift SMG population will have spectra dominated by re-emission of their prodigious optical and UV flux by the surrounding dust in a grey-body spectrum, with indices expected to be greater than 2 and more typically 3–4.

We can divide the ACT source population according to several broad spectral groups: classical steep (and steepening) spectrum sources, sources that peak within the frequency range under consideration, and sources that show flat, rising or upturned spectra.

The ACT catalogue is dominated by synchrotron-dominated blazars, which have variable flux densities. This variation in flux density is not periodic. For any single source, then, inferences about its spectrum will depend on the epoch of observation, although not biased one way or the other. For the catalogue as an ensemble, however, a spectral study may give rise to insights about the average spectral behaviour of the galaxy populations.

Table 3 summarizes the median spectral indices between pairs of frequencies for various subsets of the ACT data. In obtaining the spectral indices, we compare the deboosted flux densities from ACT with the raw flux densities from AT20G. The whole sample includes data from the 20 GHz ATCA follow-up observations taken in 2010 November (Section 2.3).

Fig. 7 shows the 5–20, 20–148 and 148–218 GHz colour-magnitude diagrams. The radio-selected AGN (black points) are predominantly characterized by steepening of the spectra, with only a few characterized by extremely flat or inverted spectra. There is a clear trend towards more negative median spectral index with increasing frequency. Magenta points, showing rising spectra between 148 and 218 GHz, denote sources ACT classified as spectrally dust dominated. They do not show up in the top two plots, indicating that these sources have flux densities falling below the detection threshold of the AT20G catalogue.

The average spectral indices between AT20G and ACT frequencies indicate an underlying source population made up of FSRQs, a type of blazar, with AGN jet pointed along our line of sight (de Zotti et al. 2010). Ejected material flows through several shocked regions in the jet which locally enhance the radiation (Marscher & Gear 1985; Valtaoja et al. 1992). The observed spectral flatness is the superposition of many components with different turnover frequencies. At frequencies greater than approximately 100 GHz, however, M11, Vieira et al. (2010) and Planck Collaboration XIII (2011) observe a steepening of the spectrum ($\alpha_{148-218} \approx -0.6$) that until now had not been conclusively shown (Tucci et al. 2011). This change is possibly due to electron energy losses in the jet (‘electron ageing’) or the transition to the optically thin regime in the extended radio lobes. The underlying physical mechanisms have been contested for more than a decade and remain the subject of ongoing study (e.g. Ghisellini & Tavecchio 2008; Nieppola et al. 2008; Sambruna et al. 2010).

Figure 7. Colour-magnitude diagrams comparing the 5–20 GHz (top), 20–148 GHz (middle) and 148–218 GHz (bottom) spectral indices for ACT-ATCA cross-identified sources. The synchrotron-dominated radio galaxy population is dominated by sources which have consistently falling SEDs towards higher frequencies.

All but one of the synchrotron-dominated ACT detections with flux density > 50 mJy have cross-identifications in AT20G. Below this flux density, the mean spectral indices of the population of ACT-AT20G cross-identified sources are biased towards the negative by the incompleteness of the AT20G catalogue below 100 mJy at 5 GHz and below 40 mJy at 20 GHz. It is therefore illustrative to further divide this subpopulation according to the 148 GHz flux density.

Fig. 8, a radio colour-magnitude diagram, plots the spectral index α_{20-148} against the 148 GHz source flux density. Black and grey points identify the M11 sources that were cross-identified with the AT20G catalogue. Black points are for sources with flux densities > 50 mJy, which represented a complete sample. Grey points denote the fainter, incomplete sample. The blue points were obtained by calculating the spectral index for the previously unmatched, lower flux density subsample, followed up with ATCA (see Table 4 for AT20G source IDs with an asterisk). The population represented by the blue points fills in the picture remarkably for the fainter (below the 50 mJy flux density at 148 GHz, below 40 mJy at 20 GHz)

Figure 8. Radio colour–magnitude diagram using 20–148 GHz spectral indices for ACT-AT20G cross-identified sources. The data are divided between flux densities at 50 mJy at 148 GHz. The low-flux sample was incomplete and suffered from selection bias that favoured sources with more negative spectral indices. Data from the ATCA follow-up study for the M11 ACT 148 GHz sources not cross-identified with AT20G are shown as green squares. The high-flux sample, denoted with black points, has a median spectral index -0.37 . Prior to ATCA follow-up observations, the lower flux ACT sources cross-identified with the AT20G catalogue (grey crosses) had a median spectral index of -0.52 . Including the follow-up data, the more complete lower flux sample has a median spectral index of -0.43 .

population, especially in the region with spectral index of approximately zero.

The unbiased $S_{148} > 50$ mJy sample has a 20–148 GHz median spectral index of $-0.36^{+0.24}_{-0.29}$. For the $S_{148} < 50$ mJy subsample prior to a follow-up with ATCA (grey points only), the 20–148 GHz spectral index was $\alpha_{20-148} = -0.52^{+0.17}_{-0.28}$. However, with the addition of the synchrotron-classified ACT-selected sources with 2010 ATCA follow-up data (grey and blue points), the full sample has 20–148 GHz spectral index $\alpha_{20-148} = -0.42^{+0.32}_{-0.26}$. This supports the hypothesis that the lower flux contingent is probing the same population of synchrotron-dominated sources (blazars), and that there is not much evolution of their spectral index with flux. The full data set suggests that the increased scatter at lower fluxes is due to variability (which will have a larger relative effect on the fluxes) and decreased S/N from flux error.

For our dust-dominated sources, we find a median spectral index of $\alpha_{148-218} = 3.7^{+0.62}_{-0.86}$. For sources detected above 5σ at both 150 and 220 GHz, SPT derives $\alpha_{150-220} = 3.35 \pm 0.7$ (Mocanu et al. 2013). These indices are consistent with the findings of Dunkley et al. (2011), where the effective index of unresolved IR emission as determined from ACT data is 3.69 ± 0.14 , and the best-fitting mean spectral indices of $\alpha_{150-220}^P = 3.86 \pm 0.23$ for Poisson-distributed sources and $\alpha_{150-220}^C = 3.80 \pm 1.3$ for the clustered component, found below the SPT detection threshold (Hall et al. 2010), a population expected to be dominated by dust-dominated sources. If we model dust emission as a modified blackbody, in the Rayleigh–Jeans (RJ) limit, the dust emissivity index is related to the effective spectral index as $\beta = \alpha - 2 = 1.7$, consistent with models of ≈ 30 K dust made from graphite and silicate grains (Draine & Lee 1984). We leave a more rigorous analysis involving redshifted

grey bodies, where the RJ limit is not as good an approximation, and the implications for star formation to future work.

8 CONCLUSION

We have described the extragalactic source population at 148 and 218 GHz found in a 455 deg^2 region of the ACT 2008 *southern strip*, centred on declination $-52^\circ 5'$. This updates the ACT 148 GHz catalogue by using the data released with D13, extends the results in M11 to two bands and treats noise as more local, which in turn yields a higher S/N. We detect 191 sources above $S/N = 5$ in at least one of the ACT 148 and 218 GHz frequency bands, spanning flux densities 14–1700 mJy (Table 4). Known redshifts are as high as ≈ 6 , with measurements ongoing. The catalogue is estimated to be 100 per cent pure and 96.8 per cent complete above 30 mJy at 148 GHz, and 97.7 per cent pure and 80.2 per cent complete above 30 mJy at 218 GHz. We have confirmed flux recovery of the pipeline and jointly deboosted the flux densities in both bands.

The multifrequency nature of our observations allows for internal classification of sources into three broad classes of sources based on their spectra: synchrotron-dominated sources (the vast majority of which are cross-identified with radio catalogues), low-redshift dust-dominated sources with *IRAS* counterparts (typically ULIRGs) and dust-dominated sources also observed by SPT or with no cross-identification, either shown or assumed to be high-redshift star-forming galaxies. This last class, only recently observed at millimetre wavelengths, has many of the properties expected of the progenitor population of massive, modern-day, elliptical galaxies, background SMGs whose flux has been magnified through gravitational lensing by a foreground galaxy or galaxy group. This interpretation, bolstered by population synthesis analyses (e.g. Thomas et al. 2005), is being validated with follow-up observations.

A comparison with other catalogues shows that 97 per cent of ACT-detected sources correspond to sources detected at lower or higher frequencies. The 148 GHz source counts are fitted reasonably well by the C2Ex radio model of Tucci et al. (2011), the most current model for radio sources. According to the analysis of the average spectral indices derived from the combined AT20G and ACT data sets, the ACT data support the case for a spectral steepening towards higher frequencies above 100 GHz for AGN. The ACT dust-dominated source population has a median spectral index, $\alpha_{148-218}$, of $3.7^{+0.62}_{-0.86}$. Properly linking these sources into the broader context of galaxy formation and evolution is of cosmological interest, and a goal of future work.

The analysis presented here uses only the 2008 data of ACT’s *southern strip*, representing only 1/6th of the data ACT obtained between 2007 and 2010. In future work, we will extend our analysis of the source population to include the full data set integrating both the southern and equatorial regions observed by ACT. The ACT *equatorial strip* overlaps with deep Sloan Digital Sky Survey Stripe 82 observations (Annis et al. 2011). Thus, as well as increasing the sky coverage and number counts for the ACT sources, future work will include joint analyses with optical data.

^aFlux density as measured directly from the ACT 148 GHz map.^bFlux density as measured directly from the ACT 218 GHz map.^cAT20G or an asterisk denotes the 2010 November follow-up observation catalogue.^dAn ACT source not cross-identified with the catalogues specified in Section 5.

Funding was also provided by Princeton University, the University of Pennsylvania and a Canada Foundation for Innovation (CFI) award to UBC. ES acknowledges support by NSF Physics Frontier Center grant PHY-0114422 to the Kavli Institute of Cosmological Physics. The PIRE programme enabled this research through exchanges between Chile, South Africa, Spain and the US. Computations were performed on the GPC supercomputer at the SciNet HPC Consortium. SciNet is funded by the Canada Foundation for Innovation (CFI) under the auspices of Compute Canada, the Government of Ontario, the Ontario Research Fund – Research Excellence and the University of Toronto. Data acquisition electronics were developed with assistance from the CFI. ACT operates in the Parque Astronómico Atacama in northern Chile under the auspices of the Comisión Nacional de Investigación Científica y Tecnológica de Chile (CONICYT).

We thank the staff at the Australia Telescope Compact Array site, Narrabri (NSW), for the valuable support they provide in running the telescope. ATCA is part of the Australia Telescope National Facility which is funded by the Commonwealth of Australia for operation as a National Facility managed by CSIRO.

This research made use of the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

ACT data products are publicly accessible through LAMBDA (<http://lambda.gsfc.nasa.gov/>) and the ACT website (<http://www.physics.princeton.edu/act/>).
